ABSTRACT

We present moderate resolution Keck spectroscopy of quasars at $z = 5.82$, 5.99 and 6.28 , discovered by the Sloan Digital Sky Survey (SDSS). We find that the Ly α absorption in the spectra of these quasars evolves strongly with redshift. To $z \sim 5.7$, the Ly α absorption evolves as expected from an extrapolation from lower redshifts. However, in the highest redshift object, SDSSp J103027.10+052455.0 ($z = 6.28$), the average transmitted flux is 0.0038 ± 0.0026 times that of the continuum level over $8450 \text{ \AA} < \lambda < 8710 \text{ \AA}$ ($5.95 < z_{\text{abs}} < 6.16$), consistent with zero flux. Thus the flux level drops by a factor of > 150 , and is consistent with zero flux in the Ly α forest region immediately blueward of the Ly α emission line, compared with a drop by a factor of ~ 10 at $z_{\text{abs}} \sim 5.3$. A similar break is seen at Ly β ; because of the decreased oscillator strength of this transition, this allows us to put a considerably stronger limit, $\tau_{\text{eff}} > 20$, on the optical depth to Ly α absorption at $z = 6$.

This is a clear detection of a complete Gunn-Peterson trough, caused by neutral hydrogen in the intergalactic medium. Even a small neutral hydrogen fraction in the intergalactic medium would result in an undetectable flux in the Ly α forest region. Therefore, the existence of the Gunn-Peterson trough by itself does not indicate that the quasar is observed prior to the reionization epoch. However, the fast evolution of the mean absorption in these high-redshift quasars suggests that the mean ionizing background along the line of sight to this quasar has declined significantly from $z \sim 5$ to 6 , and the universe is approaching the reionization epoch at $z \sim 6$.

1. INTRODUCTION

Recent discoveries of quasars at redshifts of 5.8 and greater (Fan et al. 2000, Fan et al. 2001a, hereafter Paper I) are finally allowing quantitative studies of the status of the intergalactic medium (IGM) and the history of reionization at redshifts near 6. The absence of a Gunn-Peterson trough (Shklovsky 1964, Scheuer 1965, Gunn & Peterson 1965) in the spectrum of the $z = 5.8$ quasar SDSSp J104433.4–012502.2 (SDSS 1044–0125 for brevity, Fan et al. 2000; see Goodrich et al. 2001 for an updated redshift based on the CIV line in the near-infrared) indicates that the intergalactic medium (IGM) is already highly ionized at $z \sim 5.5$, presumably by the UV ionizing photons from quasars and star-forming galaxies at high redshift. In Paper I, we used the low resolution discovery spectra of the three new quasars at $z > 5.8$, taken with the ARC 3.5m telescope at Apache Point Observatory, to show that Ly α absorption increases significantly from a redshift of 5.5 to a redshift of 6.0. In particular, the spectrum of the $z = 6.28$ quasar SDSSpJ 103027.10+052455.0 shows that in a $\sim 300\text{\AA}$ region of the Ly α forest immediately blueward of the Ly α emission line, the flux level is consistent with zero, indicating a flux decrement of $\gtrsim 50$, and suggesting a possible detection of the complete Gunn-Peterson trough. To more accurately quantify this effect, and to constrain the properties of the IGM, we have obtained higher resolution spectra of the three new $z > 5.8$ quasars using the Echelle Spectrograph and Imager (ESI; Epps & Miller 1998) on the Keck II telescope.

In section 2 we describe the observations and present the spectra of all four $z \gtrsim 5.8$ quasars in the sample of Fan et al. (2001a). We measure the emission line redshifts of the three new quasars using these spectra. In section 3, we discuss the properties of the Ly α forest in the four spectra from the point of view of the overall opacity of the IGM as a function of redshift. In section 4 we discuss the cosmological implications of the results.

2. SPECTROSCOPIC OBSERVATIONS

SDSSp J083643.85+005453.3 ($z = 5.82$), SDSSp J130608.26+035626.3 ($z = 5.99$) and SDSSp J103027.10+052455.0 ($z = 6.28$, referred to as SDSS 0836+0054, SDSS 1306+0356 and SDSS 1030+0524 throughout this paper for brevity) were selected as *i*-dropout objects from the Sloan Digital Sky Survey (SDSS, York et al. 2000) multicolor imaging data. They were further separated from cool dwarfs using follow-up *J*-band photometry, and discovery spectra were obtained using the Double Imaging Spectrograph (DIS), a low-resolution spectrograph ($R \sim 500$) on the ARC 3.5m telescope at the Apache Point Observatory (Paper I).

In March and May, 2001, we obtained moderate resolution spectra of these three high redshift quasars, using ESI on the Keck II telescope. The spectra were taken in the echellette mode of ESI. In this mode, the spectral range from 4000 to 10000 \AA is covered in ten spectral orders with a constant dispersion of $11.4 \text{ km s}^{-1} \text{ pixel}^{-1}$. With a plate scale ranging from $0.142''$ to $0.128''$ per pixel in the three reddest orders, the $1''$ slit has a footprint of $81\text{--}90 \text{ km s}^{-1}$ and the $\sim 0.7''$ typical seeing has a footprint of $57\text{--}63 \text{ km s}^{-1}$. Using the sky lines in the spectrum, we estimate that the Full Width at Half Maximum of the instrument profile

is $\sim 1.8\text{\AA}$ at $\sim 8500\text{\AA}$, indicating a spectral resolution of 66 km s^{-1} , or $R \sim 4700$, almost 10 times higher than that of the discovery spectra. Wavelength calibration is based on observations of Hg-Ne-Xe lamps and Cu-Ar lamps. The ESI has active flexure control that minimizes any drift in the wavelength calibration or fringing pattern. This is especially important for accurate sky subtraction – a crucial step in detecting the faint flux in the quasar Ly α forest region in the presence of strong sky emission lines. The spectrophotometric standard G191-B2B (Massey 1988, Massey & Gronwall 1990) was observed for flux calibration. The standard star, observed at similar airmass as the quasars, was also used for tracing the spectra in the spectral region where little flux is detected from the quasar due to strong Ly α absorption. All the observations were made at the parallactic angle. Data reduction made use of standard IRAF routines along with a suite of custom analysis routines that handle the large curvature, highly non-linear photometric response, and slight tilt of the sky lines in the ESI instrument. The dates and durations of the exposures are given in Table 1.

The three spectra are displayed in Figure 1, along with the spectrum of SDSS 1044–0125, which was observed an year earlier with the same instrument setting (Fig. 2 of Fan et al. 2000). The spectra are binned to 4\AA pixel^{-1} to improve the signal-to-noise ratio, and the flux levels are adjusted to match the z band photometry presented in Paper I. Each pixel is weighted by the inverse square of the estimated noise on that pixel when the high resolution spectrum is binned to low resolution. It is clear from a visual inspection of the four spectra that the flux level blueward of Ly α decreases with increasing redshift, and is consistent with zero flux in SDSS 1030+0524.

Using these spectra, we first determine accurate redshifts from the emission lines. As discussed in Fan et al. (2000) and in Paper I, redshift determination of $z > 5.5$ quasars using optical spectra is difficult, due to the weakness of the accessible metal emission lines and the effect of Ly α forest absorption on the Ly α emission line. The presence of associated metal absorption lines would also bias the result (Goodrich et al. 2001). The strong CIV emission line, now at $\lambda > 10000\text{\AA}$, would provide a more reliable redshift measurement, but it lies beyond our spectral coverage for all our objects.

SDSS 1044–0125. As mentioned above, the displayed spectrum is from Fan et al. (2000). Djorgovski et al. (2001) present a higher signal-to-noise spectrum of SDSS 1044–0125, which shows the increasing optical depth of the Ly α forest with redshift particularly well.

SDSS 0836+0054. A strong OI+SiII $\lambda 1302$ emission line is detected at $\lambda = 8873 \pm 1\text{\AA}$, with a rest-frame equivalent width (EW) of $4.2 \pm 0.1\text{\AA}$. The Ly α +NV emission line is very broad, with the peak wavelength of the Ly α component at $\sim 8230\text{\AA}$, and $\text{EW} = 70 \pm 3\text{\AA}$. We adopt a redshift of 5.82, using the central wavelength of OI line, and a redshift error of 0.02, considering the uncertainty using a single line for redshift. The peak of the Ly α emission line is consistent with this redshift. The EW of OI+SiII is comparable to that of the average of $z \sim 4$ quasars (3.2\AA , Schneider, Schmidt & Gunn 1991).

SDSS 1306+0356. The strong Ly α +NV emission line shows a separate NV $\lambda 1240$ component. We determine the

FIG. 1.— Optical spectra of $z \gtrsim 5.8$ quasars observed with Keck/ESI, in the observed frame. The spectra have been smoothed to 4 \AA pixel^{-1} , and have been normalized to the observed z band flux. The spectrum of SDSS1044-0125 has been taken from Fan et al. (2000). In each spectrum, the expected wavelengths of prominent emission lines, as well as the Lyman limit, are indicated by the dashed lines.

central wavelengths and EWs of Ly α and NV by fitting two Gaussian profiles to the wavelength range redward of the peak of Ly α emission, i.e., the region not affected by the Ly α forest absorption. The wavelength ratio of the two components is fixed in the fitting procedure. We find $z_{em} = 5.99$, $EW(\text{Ly}\alpha) = 38.1 \pm 14.9 \text{ \AA}$, and $EW(\text{NV}) = 17.9 \pm 6.3 \text{ \AA}$. No obvious OI+SiII emission line is detected; any emission line there is probably affected by the CIV absorption feature at the same wavelength (see below). A possible SiIV λ 1402 feature is detected at $\sim 9800 \text{ \AA}$, but it is difficult to fit its profile due to the weakness of the line and possible absorption lines nearby. We therefore adopt a redshift of 5.99 ± 0.02 for SDSS 1306+0356.

In the spectrum of SDSS 1306+0356, we notice a strong absorption feature at $\sim 7130 \text{ \AA}$, where over $\sim 80 \text{ \AA}$, there is no detectable flux. The rest-frame equivalent width is $\sim 15 \text{ \AA}$, typical for a damped Ly α system, at a redshift of $z_{abs} = 4.86$. A strong absorption feature is detected at $\lambda = 9080 \text{ \AA}$, corresponding to CIV absorption at the same redshift. This feature is double peaked in absorption, consistent with the $\lambda\lambda 1548, 1551$ components of the CIV doublet, although the signal-to-noise ratio is low at that wavelength. This system, if confirmed by high signal-to-noise ratio spectroscopy, is the highest-redshift damped Ly α system known (the previous record holder was at $z = 4.47$; Péroux et al. 2001; Dessauges-Zavadsky et al. 2001). The two other doublet absorption features at $\sim 9900 \text{ \AA}$ and $\sim 8960 \text{ \AA}$, are identified as MgII absorptions at $z = 2.53$ and 2.20 , respectively. Note that other spectra in this paper also show various absorption features redward of Ly α emission. The detailed identifications of these metal lines are beyond the scope of this paper.

SDSS 1030+0524. In Paper I, we presented the Keck/NIRSPEC J -band spectrum of this object, in which a strong CIV feature ($EW = 31.5 \pm 8.6 \text{ \AA}$) is detected, at $z = 6.28 \pm 0.02$. The optical spectrum shows a separate NV emission line, and possible detection of OI+SiII and SiIV lines at the same redshift. We measure $EW(\text{Ly}\alpha) = 40.9 \pm 7.4 \text{ \AA}$, and $EW(\text{NV}) = 16.9 \pm 4.0 \text{ \AA}$, by fitting Gaussian profiles to the blended Ly α +NV emission line.

Paper I discusses the implication of the detection of metal emission lines, in particular, that of NV emission, to the metallicity of the quasar environment. Assuming a power law continuum of $f_\nu \propto \nu^{-0.5}$, the flux ratio NV/CIV is 0.74 ± 0.27 , consistent with a super-solar metallicity $Z \gtrsim 3Z_\odot$, according to the calculations of Hamann & Ferland (1993). Note, however, these calculations assume a single-zone photo-ionization model, and might be affected by the uncertainties in heavy element ratios, as well as possible enhancement of NV flux by resonant scattering from the red wing of the Ly α emission line (Krolik & Voit 1998).

3. NEUTRAL HYDROGEN ABSORPTION

In Paper I, we calculated the average absorption in the Ly α forest region based on the ARC 3.5m discovery spectra. Here we carry out these calculations with the Keck spectra. The results are summarized in Table 2. The table includes the measurement of the D_A and D_B parameters following Oke & Korycansky (1982), the average flux decrement in the Ly α and Ly β forest regions, respectively, as well as the transmitted flux ratio $[\mathcal{T}(z_{abs})]$ defined in

Paper I, measured in the highest redshift window in each quasar that is not affected by the Ly α emission line and the proximity effect. The definitions of these quantities are given in Paper I. The transmitted flux ratio is measured in the redshift range $z_{em} - 0.4 < z_{abs} < z_{em} - 0.2$ for all objects except SDSS 1030+0524, for which the range is $5.95 < z_{abs} < 6.16$. Additional measurements of this quantity along the line of sight to each quasar at lower redshift are illustrated in Figure 2. All the measurements here and below assume an intrinsic quasar continuum $f_\nu \propto \nu^{-0.5}$ ($f_\lambda \propto \lambda^{-1.5}$), with the continuum normalized at rest frame wavelength of $1270 \pm 10 \text{ \AA}$, a region free of major emission lines. The unknown continuum shape is a source of systematic error. However, for a wavelength window close to the Ly α emission, and in the regime in which $\mathcal{T}(z_{abs}) \ll 1$, this error is much smaller than the cosmic variance of \mathcal{T} (see below). As in Paper I, the error bars on the D_A and D_B measurements reflect the uncertainties of the continuum shape in the Ly α forest region, while the error bars on $\mathcal{T}(z_{abs})$ include only the photon noise. In calculating the average flux and the photon noise, the signal in each pixel is weighted by the inverse square of the estimated noise level in that pixel. The values in Table 2 are consistent with the measurements in Paper I, albeit with errors lower by a factor of ~ 5 .

In Table 2, we also include the measurement of the redshift of the Lyman Limit System (z_{LLS}), following the method described in Fan et al. (2000, §4.1). Note, however, at $z \sim 6$, the flux level at the rest-frame 912 \AA is so low due to the presence of numerous Ly α forest lines from lower redshift, that this measurement is rather uncertain. The quasar spectra are consistent with no flux almost immediately blueward of rest-frame 912 \AA .

Figure 2 presents the evolution of the transmitted flux ratio \mathcal{T} and effective optical depth $\tau_{eff} (\equiv -\ln(\mathcal{T}))$ as a function of redshift z_{abs} . The average absorption evolves strongly with redshift. At $z_{abs} \sim 3.5$, $\mathcal{T} \sim 0.4$ (e.g. Rauch et al. 1997). It decreases to $\mathcal{T} \sim 0.25$ at $z \sim 4.5$ (Songaila et al. 1999). At $z \sim 5.0$, $\langle \mathcal{T} \rangle \sim 0.12$ from Figure 2, and at $z \sim 5.5$, $\langle \mathcal{T} \rangle \sim 0.07$. The scatter of \mathcal{T} at the same redshift is larger than implied by photon noise or uncertainty of the continuum shape, suggesting that the error in \mathcal{T} is dominated by cosmic variance. Zuo (1993) calculated the scatter of the transmitted flux given the number density and column density distribution of Ly α clouds. Using Eq. (9) in that paper, we find that at $z \sim 5.5$, for $\mathcal{T} \sim 0.10$, $\sigma(\mathcal{T}) \sim 0.03$, comparable to the scatter seen in Figure 2. For $\mathcal{T} \ll 1$, $\sigma(\mathcal{T})$ is comparable to \mathcal{T} itself, and decreases rapidly toward higher redshift.

The only measurements of \mathcal{T} at $z > 5.7$ come from the highest redshift object SDSS 1030+0524. It shows that $\mathcal{T}(z_{abs} = 5.75) = 0.03$. The most dramatic change in \mathcal{T} , however, comes from the measurement at $z \sim 6$; over the redshift range $5.95 < z_{abs} < 6.16$, the average transmitted flux $\mathcal{T} = 0.0038 \pm 0.0026$. This 1.5σ “detection” is in fact consistent with zero in our estimation; indeed, slight changes in the way we did our sky subtraction caused the value to change by of order 1σ . Thus there is no detectable flux over the wavelength range of $8450 < \lambda < 8710 \text{ \AA}$, corresponding to a flux decrement of > 150 from the continuum level, or equivalently, to a lower limit ($1-\sigma$) on the Gunn-Peterson optical depth due to neutral hydrogen in

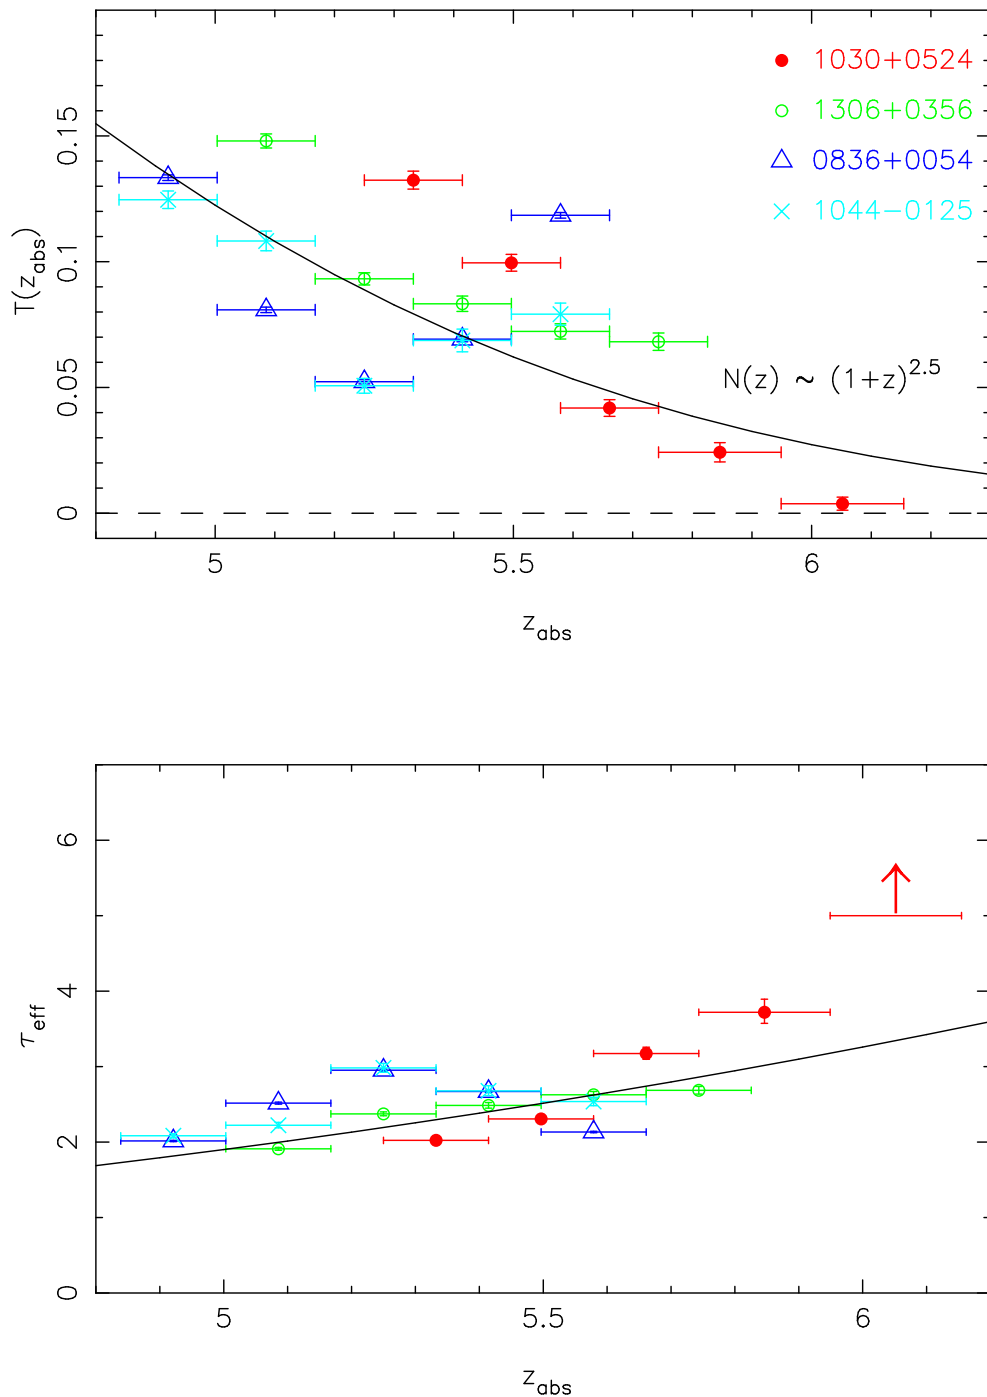

FIG. 2.— Evolution of transmitted flux ratio and effective Gunn-Peterson optical depth as functions of redshift. The solid line is the expected evolution if the number density of Ly α clouds increases as $N(z) \propto (1+z)^{2.5}$. No flux is detected in the spectrum of SDSS 1030+0524 at $z_{\text{abs}} \sim 6$, indicating $\tau_{\text{eff}} > 5.0$. The non-detection of flux in the Ly β trough gives a substantially stronger 1σ upper limit of $\tau_{\text{eff}} > 20$.

the IGM of $\tau_{GP} > 5.0$. At $\lambda > 8750\text{\AA}$, the flux is detectable again, presumably due to the effect of the ionizing photons from the luminous quasar itself (§4). This result confirms the measurement based on the discovery spectrum (Paper I), in which we found $\mathcal{T} = 0.003 \pm 0.020$. This is the first detection of a complete Gunn-Peterson trough, in the sense that no flux is detected over a large wavelength range in the Ly α forest region, indicating that the effective Gunn-Peterson optical depth caused by neutral hydrogen in the IGM, τ_{eff} , is much larger than one.

Figure 3 shows the sky-subtracted two-dimensional spectrogram from the ninth order of the ESI data; note the complete absence of detected flux blueward of the Ly α emission line. Figure 3 also shows the one-dimensional spectrum and the corresponding estimated error per pixel (shaded) of SDSS 1030+0524 over the redshift range $5.75 < z < 6.25$ for both Ly α and Ly β . As evident from the figure, the average flux level is consistent with zero for $5.95 < z < 6.16$ at both lines (8450 – 8710 Å for Ly α , and 7130 – 7350 Å for Ly β).

The effective continuum at Ly β is affected by the Ly α forest. The effective Ly α redshift at 7240 Å, the center of the Ly β trough, is $z \approx 5$. Figure 2 shows that at that redshift, the transmission of the Ly α forest is roughly 12%, albeit with large scatter (see also Songaila et al. 1999). Taking this into account, and again extrapolating the quasar continuum from redward of Ly α emission assuming $f_\lambda \propto \lambda^{-1.5}$ gives a measured transmitted flux ratio in the Ly β trough of -0.002 ± 0.020 , a clear non-detection. The error does not include the uncertainty in the transmission of Ly α at $z = 5$, which we estimate to be approximately 20% in τ_{eff} based on the scatter seen in Fig. 2.

The ratio of oscillator strengths of the Ly α and Ly β lines is 5.27 (Verner, Verner, & Ferland 1996). Thus we can convert the transmitted flux ratio in the Ly β forest region to an *equivalent* 1σ lower limit to the optical depth in the Ly α forest region of $\tau_{eff} > 20$ (albeit with an uncertainty due to the limits of our model for the intrinsic spectrum). This limit is, in fact, considerably stronger than the limit obtained directly from the Ly α forest itself.

At $\lambda < 6980\text{\AA}$, there appears to be another break (Figure 1); this is the start of the corresponding Ly γ Gunn-Peterson trough. We have not attempted to obtain a quantitative optical depth for this line, due to the extreme overlapping absorption from both the Ly α and Ly β forests.

Our ability to constrain the upper limit of the flux in the Ly α and Ly β forest regions, and the corresponding lower limit to the Gunn-Peterson optical depth, depends on the reliability of sky subtraction. In this case, the expression “black as night” has special significance because invariably, upper limits to brightness come down to the accuracy with which one can subtract the sky. Unfortunately, the night sky is not very black, especially in the near IR region, where the sky emission is concentrated in a series of very bright OH lines that nearly blanket the spectrum. At the ESI resolution, the peak of the strongest sky lines at 8000 – 9000 Å can be a factor of > 50 stronger than that of the darker region between lines. The high spectral resolution of ESI enables us to resolve the much darker regions between strong sky lines and limits the number of pixels affected by the sky lines. The pixels affected by

strong sky lines are assigned much smaller weights when we calculate the average flux and effective optical depth. It is our considered opinion that in this instance, the data reduction posed no unusual difficulties and that the faint to nonexistent flux levels seen blueward of Ly α are reliable. These problems are less severe in the spectral region of the Ly β trough, and as we’ve seen, the two troughs give consistent limits on the mean optical depth.

4. DISCUSSION

The Gunn-Peterson (1965) optical depth in a uniformly distributed IGM is given by

$$\tau_{GP}(z) = 1.8 \times 10^5 h^{-1} \Omega_M^{-1/2} \left(\frac{\Omega_b h^2}{0.02} \right) \left(\frac{1+z}{7} \right)^{3/2} \left(\frac{n_{\text{HI}}}{n_{\text{H}}} \right). \quad (1)$$

Only a small fraction of neutral hydrogen component in the IGM is needed to have $\tau_{GP} \gg 1$ and give rise to a complete Gunn-Peterson trough. Therefore, the existence of a Gunn-Peterson trough by itself does not prove that the object is observed prior to the reionization epoch. Even if the neutral fraction were independent of redshift, one still expects the transparency of the Ly α forest to decrease with increasing redshift. In reality, the expansion of the universe and the increase in the ionizing background cause the neutral hydrogen fraction to decrease towards low redshift (see below). The observed redshift evolution of the Gunn-Peterson optical depth in the spectrum of SDSS 1030+0524 allows us to answer an important question: Is the amount of Ly α forest absorption at $z \sim 6$ consistent with a simple extrapolation from the observations at lower redshifts? Or does it indicate a more dramatic change in the state of the IGM?

Assuming that the number density of Ly α forest lines evolves with redshift as $(1+z)^\gamma$, where $\gamma \sim 2.5$ at $z \sim 4$, the effective optical depth evolves as $(1+z)^{\gamma+1}$ (Zuo & Phinney 1993, Zuo 1993). The solid line in Figure 2 shows an extrapolation of the optical depths to higher redshifts using this simple model. It is evident that the $z \sim 6$ value from SDSS 1030+0524 deviates from this extrapolation; the observed absorption at $z \sim 6$ is stronger than that predicted by this model assuming an ionization fraction that remains constant with redshift. A natural explanation for this difference is that the ionization fraction increases with time, i.e., the IGM was more neutral at earlier times.

Assuming that the hydrogen gas in the IGM responsible for the Ly α forest absorption is in photoionization equilibrium, wherein photoionization of the neutral hydrogen by the UV background is balanced by recombination, one can express $(n_{\text{HI}}/n_{\text{H}})$ in equation (1) in terms of the ionizing background. Doing so, the Gunn-Peterson optical depth of a uniform IGM can be expressed as (Weinberg et al. 1997),

$$\tau_{GP} = 5.9 \times 10^{-4} H_0 (1+z)^6 H(z)^{-1} h^{-1} T_4^{-0.7} (\Omega_b h^2 / 0.02)^2 \Gamma_{-12}^{-1}. \quad (2)$$

Here, $H(z)$ is the Hubble constant at redshift z , T_4 is the temperature of the IGM gas in units of 10^4K , and Γ_{-12} , the photo-ionization rate of hydrogen in units of 10^{-12}s^{-1} , depends on the shape and amplitude of the ionizing background. Thus, in a given background cosmology, the observed evolution of the Gunn-Peterson optical depth can be used to measure the redshift evolution of the ionizing

FIG. 3.— Gunn-Peterson trough in the spectrum of SDSS 1030+0524 observed with Keck/ESI. Both the $\text{Ly}\alpha$ and $\text{Ly}\beta$ absorption regions are shown. The bottom panel shows the sky-subtracted two-dimensional spectrum in the $\text{Ly}\alpha$ region. The $\text{Ly}\alpha$ data come from the ninth order of the echellette spectrum and cover the wavelength range 8200Å to 8810Å. The $\text{Ly}\beta$ data are the result of combining orders 7 and 8 and cover the wavelength range 6920Å to 7440Å. The green shaded areas are the 1σ noise bands in the extracted spectra. The spectrum is very black over the redshift range $5.95 < z < 6.16$.

background (e.g., McDonald et al. 2000). A more accurate determination of the ionizing background should also model the gravitational evolution of the Ly α forest with redshift. Recently, McDonald & Miralda-Escudé (2001) used the transmitted flux measurement to calculate the evolution of ionizing background at $z < 5.2$. In a separate paper (Fan et al. 2001b), we use both semi-analytic models and cosmological simulations to investigate the evolution of the ionizing background at higher redshifts, using the measured transmitted flux ratios and effective optical depths at $z \sim 6$.

As discussed by Miralda-Escudé (1998), the spectra of sources observed prior to complete reionization should show the red damped wing of the Gunn-Peterson trough in the red side of Ly α , due to the very large optical depth. This damped wing would, in principle, suppress the Ly α emission line. However, as shown in Madau & Rees (2000) and Cen & Haiman (2000), luminous quasars such as those discussed in this paper would ionize the surrounding regions and create HII regions of radius several Mpc (the “proximity” effect; Carswell et al. 1982). The presence of these quasar HII regions results in a much higher transmission redward of Ly α ; thus the emission line profile is less affected by the red damped wing (see also Fan et al. 2001b). Therefore, the presence of the Ly α emission line, and the absence of the red damped wing, are not by themselves indicators that the IGM was already ionized at this redshift. The true extent of the proximity effect in SDSS 1030+0524 is probably best defined by the transmission of Ly β emission at a redshift of 6.18 (see Fig. 3).

The size of the HII region associated with the quasar depends on the luminosity and lifetime of the quasar and the clumpiness of the IGM. In principle, we could use the proximity effect to constrain the amplitude of the ionizing background (Bajtlik, Duncan & Ostriker 1988), by determining the distance from the quasar at which the optical depth of the Ly α forest is half that in the Gunn-Peterson trough. However, we only have a lower limit on the latter, and so at best, we can only put a lower limit on the distance, and thus an upper limit on the ionizing background. We have calculated this upper limit, and find that it gives a much weaker constraint than comparing the data with detailed simulations (Fan et al. 2001b). Further, clumpiness of the gas distribution near the quasar on these length scales will also increase the absorption blueward of Ly α , and hence lead to an artificially higher estimate of the ionizing background.

Could any local effect produce the apparent Gunn-Peterson trough in the spectrum of SDSS 1030+0524? A 300Å region at $z \sim 6$ corresponds to a comoving distance of $\sim 70h^{-1}$ Mpc ($\Omega = 0.3$, $\Lambda = 0.7$), much larger than any large scale structure at that redshift. It is also un-

likely to be a very strong damped Ly α absorption system, as we do not see any corresponding metal lines (such as SiIV λ 1402). We are not aware of any known damped Ly α absorption line at lower redshifts with an EW of $\sim 300\text{\AA}$. At $z_{\text{abs}} \sim 6.05$, it would have a rest frame EW of $\sim 42\text{\AA}$, and $N_{\text{HI}} \sim 10^{21.5} \text{ cm}^{-2}$. Using the statistics of Storrie-Lombardi, Irwin & McMahon (1996), we expect to find only 0.02 such systems per unit redshift at $z \sim 6$. Moreover, one would expect to see associated metal lines from such a strong absorber, which are clearly not present.

However, we emphasize that the complete Gunn-Peterson trough is observed in only one (the highest-redshift) object, and if the reionization is non-uniform, one may not see exactly the same dependence of the Gunn-Peterson trough with redshift along other lines of sight. In order to gain a more complete understanding of the IGM at $z \gtrsim 6$, more lines of sight are clearly needed. The SDSS is expected to find ~ 20 quasars at $z \gtrsim 6$ over the course of the survey (Paper I), so we can look forward to opportunities to study this question in detail over the next few years.

The Sloan Digital Sky Survey (SDSS) is a joint project of The University of Chicago, Fermilab, the Institute for Advanced Study, the Japan Participation Group, The Johns Hopkins University, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Princeton University, the United States Naval Observatory, and the University of Washington. Apache Point Observatory, site of the SDSS telescopes, is operated by the Astrophysical Research Consortium (ARC). Funding for the project has been provided by the Alfred P. Sloan Foundation, the SDSS member institutions, the National Aeronautics and Space Administration, the National Science Foundation, the U.S. Department of Energy, the Japanese Monbukagakusho, and the Max Planck Society. The SDSS Web site is <http://www.sdss.org>. We acknowledge support from NSF grants AST-98-02791 and AST-98-02732 and the Institute of Geophysics and Planetary Physics (operated under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract No. W-7405-Eng-48) (RHB), from NSF grant PHY00-70928 and a Frank and Peggy Taplin Fellowship (XF), from the Space Telescope Science Institute (RLW), and from NSF grant AST-0071091 (MAS). We wish to thank an anonymous referee for correcting an error in the interpretation of the Ly β absorption. Thanks to David Helfand for his support during the Keck observing run and for cooking RHB and RLW a fine dinner while we were observing.
